Abstract: The goal of this study was to develop a clinically relevant non-human primate (baboon) stroke model and multi-parametric MRI protocols on a clinical scanner with long-term goals to better model human stroke and facilitate clinical translations of novel therapeutic strategies. Baboons were chosen because of their relatively large brain volume and that they are evolutionarily close to humans. Middle cerebral artery occlusion (MCAO) was induced using a minimally invasive endovascular approach to guide an inflatable balloon catheter into the MCA and either permanently or transiently inflate the balloon. Using multimodal MRI, including perfusion and diffusion imaging, the spatiotemporal dynamic evolution of the ischemic lesions in permanent and transient occlusion experiments in baboons were investigated. Perfusion-diffusion mismatch, which approximates the ischemic penumbra, was detected. In the permanent MCAO group (n = 2), the mean infarct volume was 29 ml (17% of total brain volume) whereas in the transient MCAO group (n = 2, 60 or 90 min of occlusion), the mean infarct volume was 15 ml (9% of total brain volume). Substantial perfusion-diffusion mismatch tissue (~50%) was salvaged by reperfusion compared to permanent MCAO. This baboon stroke model has the potential to provide a clinically relevant test bed to better design clinical studies, guide clinical diagnosis and improve treatment time windows in patients.

INTRODUCTION

Ischemic stroke is a major cause of death and a leading cause of long-term disability worldwide, constituting a major societal burden. One of the major goals of stroke research is to develop clinically relevant stroke models and find ways to identify viable tissue in a timely manner using noninvasive imaging methods. The ischemic penumbra, tissue at risk surrounding the initial ischemic core, is potentially salvageable if treated in a timely manner [1]. Diffusion-weighted imaging (DWI), in which contrast is based on early changes in the apparent diffusion coefficient (ADC) of water, is a powerful tool for early detection of ischemic brain injury [2]. Ischemic lesions are apparent as regions of diffusion hyperintensity in diffusion weighted images and hypointensity in apparent diffusion coefficient maps. A stroke lesion is characterized by regions of decreased ADC, and the signal intensity within this region may be quite inhomogeneous. Often there is an infarcted lesion core (ADC decrease of 30-50% from baseline) and a hypoperfused lesion periphery (mild to moderate decrease in ADC) [3].

Perfusion-weighted imaging (PWI) highlights brain tissue regions with abnormal or deficient cerebral blood flow (CBF). Tissue surrounding by regions of severely decreased diffusion abnormality that have a perfusion deficit but no diffusion abnormality exhibit a phenomenon referred to as the “perfusion-diffusion mismatch”, which has been shown to approximate the ischemic penumbra [4-6].

Experimental stroke models are instrumental in the development of imaging tools to identify viable tissue, to study stroke pathophysiology, and to test novel interventions under controlled experimental conditions. The availability and ease of manipulation of rodent models have greatly advanced our understanding of cerebral ischemia. While numerous treatments have been shown to be effective in rodent stroke models, none, with the exception of recombinant tissue plasminogen activator (rtPA), has proven to be effectively clinically. A possible explanation is that rodent stroke models may not sufficiently reflect the complexity of human neurophysiology in stroke. The Stroke Therapy Academic Industry Roundtable (STAIR) has recommended that new stroke intervention strategies be tested on animals that are evolutionarily closer to humans, such as nonhuman primates (NHPs), before clinical trials [7]. NHP brains share more similar vascular anatomy and neurophysiological function to humans compared to other lower animal species, such as rodents. Thus, NHP stroke characteristics, in principle, should better model human stroke, providing an important preclinical test bed to
accelerate translation of novel intervention strategies to clinical practices.

NHPs have been used as stroke models [8-15] but studies in which MRI, beyond basic anatomical imaging, has been used are sparse. Changes in perfusion, diffusion and/or fractional anisotropy in marmosets [9, 16], macaque [15, 17, 18] and baboon [19] stroke models have been reported. However, studies that show the perfusion-diffusion mismatch phenomenon in NHP stroke models have not been, to our knowledge, systematically investigated.

The goal of this study was to develop a baboon stroke model and multi-parametric MRI protocols on a clinical scanner with the long-term goals to better model human stroke and facilitate clinical translations of novel therapeutic strategies. Baboons were chosen because they have large brain volumes (i.e., more than twice that of macaques) with extensive cortical folding and the integrated circularly polarized body coil as the receiver. The animal was periodically deflated and withdrawn after 60 or 90 min of occlusion. After stroke surgery and during MRI, isoflurane was lowered to 0.8%-1.0% and added anesthetist with vecuronium (0.2 mg/kg bolus and 0.02 mg/kg as needed). Rectal temperature was maintained within normal physiological ranges (37-38 °C) using a feedback-regulated circulating warm-air blanket. ETCO2, O2 saturation, heart rate, and respiration rate were continuously monitored with an MRI-compatible physiological monitor device (Precess, InVivo, Orlando, FL, USA) during imaging. Blood gases and blood glucose were typically sampled once or twice during stroke surgery and during MRI. All physiological parameters were maintained within normal ranges.

MATERIALS AND METHODOLOGY

Stroke Model

Four normal female baboons (Papio hamadryas spp., 14-19 kg, 16 ± 2 kg) were studied with approval from the Institutional Animal Care and Use Committee of the University of Texas Health Science Center at San Antonio. Anesthesia was induced with ketamine (1.0-1.2 c.c., i.m.) for intubation and catheterization for fluid supplementation. Animals were mechanically ventilated and anesthetized with 1.5%-2.0% isoflurane in medical air during surgical cannulation of the femoral artery. End-tidal CO2 (ETCO2), O2 saturation, heart rate, and respiration rate were continuously monitored during surgery.

Permanent (n = 2) or transient (60- or 90-min, n = 2) middle cerebral artery occlusion (MCAO) was induced using minimally invasive endovascular techniques. Occlusion on the right or left MCA was determined randomly among different animals. Access to the right common femoral artery was affected using a micropuncture set and the Seldinger technique. A 5 Fr vascular sheath was inserted into the femoral artery over a 0.035” guide wire (Bentson, AngioDynamics, Latham, NY, USA). Selective catheterization of the ICA was accomplished using a 5 Fr catheter (VER135, Cordis, Bridgewater, NJ, USA) over the guide wire. Selective anterior cerebral angiogram and road mapping (Siemens SIEMOBIL Compact L) were performed by injecting contrast media (Omnipaque, GE Healthcare, Buckinghamshire, UK) through the guiding catheter at the ICA. A smaller HyperGuide balloon catheter (3x10 mm, EV3, Irvine, CA, USA) was inserted over its 0.010” guide wire, coaxially through the guiding catheter into the MCA. The balloon catheter was inflated to occlude the M2 segment of the MCA. Occlusion was confirmed with an anterior cerebral angiogram. The balloon catheter (which is not MRI compatible) was deflated and withdrawn after 60 or 90 min of occlusion. After stroke surgery, all of the catheters were removed and the animal was transported to the MRI suite down the hall. Non-reperfusion was subsequently confirmed in two animals (permanent MCAO group, 60- or 90-min occlusion before withdrawing the occluder) and successful reperfusion was confirmed in the other two animals (transient MCAO group) throughout the MRI studies using magnetic resonance angiography (MRA).

The animal preparations for MRI studies in baboons have been described previously [22, 23]. Briefly, the animal was positioned supine and secured in a custom-made, MRI compatible animal holder and stabilized with ear bars, a mouth bar and padding around the head before transportation. During MRI, isoflurane was lowered to 0.8%-1.0% and added anesthetist with vecuronium (0.2 mg/kg bolus and 0.02 mg/kg as needed). Rectal temperature was maintained within normal physiological ranges (37-38 °C) using a feedback-regulated circulating warm-air blanket. ETCO2, O2 saturation, heart rate, and respiration rate were continuously monitored with an MRI-compatible physiological monitor device (Precess, InVivo, Orlando, FL, USA) during imaging. Blood gases and blood glucose were typically sampled once or twice during stroke surgery and during MRI. All physiological parameters were maintained within normal ranges.

MRI Acquisition

MRI studies were performed on a clinical 3T Siemens TIM-Trio (Siemens Medical Solutions, Erlangen, Germany) using a standard 12-channel human head coil as a receiver and the integrated circularly polarized body coil as the transmitter. A 30-min block of MRI acquisitions included anatomical (3D high-resolution T1-weighted images and T2-weighted fluid-attenuated inversion recovery (FLAIR) images), perfusion (pseudo-continuous arterial spin labeling, pCASL), diffusion MRI, and MRA. Anatomical T1-weighting images were acquired using the MPRAGE pulse sequence with TR/TE = 2100/3.1 ms, flip angle = 12°, Ti = 1100 ms, FOV = 16x19.2x19.2 cm2, 1 mm isotropic spatial resolution and NEX=2. T2-weighted FLAIR images were acquired with TR/TE/TI = 4000/176/1800 ms, 1x1x2 mm3 spatial resolution. pCASL images were acquired using a single-shot gradient-echo EPI with TR/TE = 3500/16 ms,
labeling duration = 2.1 sec, 12 contiguous slices with 4 mm slice thickness, matrix = 64 × 64, FOV = 12.8 × 12.8 cm (2×2×4 mm³ resolution), labeling offset = 60 mm, and post-labeling delay = 700 ms as described previously [22]. Diffusion-weighted MRI was acquired using TR/TE = 4700/89 ms, b-value = 0 s/mm² and 1100 s/mm², 30 directions, spin-echo EPI read-out with 2 mm isotropic resolution.

Data Analysis

Data were processed using custom codes written in MATLAB (The MathWorks Inc., Natick, MA, USA). Quantitative cerebral blood flow was calculated as described in Wey et al. [22]. Apparent diffusion coefficient maps were calculated as described by Meng et al. [24]. Final infarct (corrected for edema as described in [24]) was determined on T2-FLAIR images on each of their last time point before euthanasia. Lesion volumes were determined by three independent observers manually drawing region-of-interests (ROIs) based on perfusion (CBF maps) and diffusion (ADC maps) images at all time points. ROIs of the infarct, defined by the endpoint T2-FLAIR images, were used for plotting temporal progression of MRI parameters.

RESULTS

The animal physiology was maintained within normal ranges before and after MCAO as well as after recovery of the transient MCAO group. Animals regained consciousness after anesthetics were discontinued and had the ability of self-feeding within 1 hour after they were awoken. One animal in the transient MCAO (60 min occlusion) showed a minor sign of movement deficit of the affected arm while the other (90 min occlusion) showed hemiparesis of both the affected arm and leg.

Fig. (1) shows the cerebral angiogram of the brain of one animal with a permanent occlusion. Angiograms clearly show the patent right ICA (Fig. 1a, dashed arrow) and cerebral vasculature in the MCA territory. The position of the balloon is between the two radiopaque markers in the subtracted image (Fig. 1b, arrow). MCA occlusion, after balloon inflation, is angiographically confirmed by the absence of x-ray contrast distally (Fig. 1c, circled region). In the contralateral hemisphere, quantitative CBF and ADC remained unchanged across all time points (data not shown). Fig. (2) shows representative MRA, CBF, and ADC maps at 30 min post-reperfusion, and the T2-weighted FLAIR image of the brain, at end-point, from a transient MCAO animal (90 min MCAO). An apparent post-ischemic early hyper-perfusion, as compared with the normal hemisphere, was observed within the previously occluded brain territory in this animal, indicative of efficient recanalization. The hypointense region in the ADC map indicates the ischemic zone. At 24 hours, T2-weighted FLAIR images reveal the infarct territory.

In the contralateral hemisphere, quantitative CBF and ADC remained unchanged across all time points (data not shown). Fig. (2) shows representative MRA, CBF, and ADC maps at 30 min post-reperfusion, and the T2-weighted FLAIR image of the brain, at end-point, from a transient MCAO animal (90 min MCAO). An apparent post-ischemic early hyper-perfusion, as compared with the normal hemisphere, was observed within the previously occluded brain territory in this animal, indicative of efficient recanalization. The hypointense region in the ADC map indicates the ischemic zone. At 24 hours, T2-weighted FLAIR images reveal the infarct territory.

Fig. (3) shows lesion volumes from the permanent MCAO group. Hypointense regions within the CBF and ADC maps 4.5 hrs after occlusion indicate the ischemic territories. The time courses of the lesion volume evolution (from one animal) indicated that the CBF-defined lesion remained relatively unchanged whereas the ADC-defined lesion volume, which was initially small, grew over time to that of the CBF-defined volume. The anatomical difference between CBF and ADC abnormalities, i.e., the perfusion-diffusion mismatch, was substantial, diminished over time, and disappeared by 6 hours post-occlusion. The average final infarct volume was ~29 mL from two animals (~17% of total brain volume).

Fig. (4) shows the lesion volumes from the transient MCAO group. Hypointense regions in the ADC maps 1 hr after reperfusion indicate the ischemic territories. Hyper- and hypo-perfusion, as compared with the normal hemisphere, were observed after reperfusion (Fig. 4a). The time course of the ADC-defined lesion volume (from one animal, 60 min MCAO) was markedly different from that of the permanent MCAO group. ADC-defined lesion volume decreased with time during the first few hours after reperfusion and peaked 1 day after stroke, and was followed by a secondary decrease on days 3 and 7, likely due to ADC renormalization. The infarct volume was defined by the endpoint (days after stroke). The T2-weighted FLAIR image volume was slightly larger than the ADC-defined lesion volume. The final infarct volume defined by T2-weighted FLAIR was ~4 mL in this representative animal (60 min MCAO), and ~26 mL in the other animal of the MCAO group (90 min MCAO, Fig. 2).

Fig. (1). Cerebral x-ray angiography (fluoroscopy) with an anterior-posterior view during stroke procedures: (a) right hemisphere cerebral angiogram with contrast injected via the right carotid artery before occlusion, (b) subtracted digital radiography showing the position of the balloon (arrow), (c) right hemisphere cerebral angiogram with contrast injected in the right carotid artery after balloon occlusion of the middle cerebral artery.
The averaged final infarct volume, defined by T2-weighted FLAIR, was ~15 mL from the two animals (~9% of total brain volume), indicating that reperfusion salvaged substantial mismatch tissue compared to permanent MCAO.

DISCUSSION

This study describes a minimally invasive surgical procedure to induce permanent and transient MCAO in a clinically relevant, large non-human primate (baboon) stroke model and a multimodal MRI protocol to longitudinally characterize ischemic evolution. Perfusion-diffusion mismatch in the MR images, which approximated the ischemic penumbra, was demonstrated. A substantial amount of the mismatched tissue was salvaged by early reperfusion compared to the permanent MCAO model.

In this baboon model, permanent MCAO, the perfusion-diffusion (PWI-DWI) mismatch detected was similar to those reported in humans and rodents. The mismatch volume progressively increased for up to 6 hours post-occlusion, in contrast to mismatch volumes in rodent models which lasted up to 3 hours post-occlusion [25]. In humans, PWI-DWI mismatch is often detected in the acute stroke phase (~6-12
hours after stroke onset), and it has been reported that the frequency of detection decreased with time [26]. The temporal topography of PWI-DWI mismatch in humans appeared more similar to that observed in baboons than that reported in rodents.

Recannalization salvaged a substantial portion of tissue immediately after reperfusion when compared with those subjects with infarcts but without reperfusion. The ADC-defined lesion decreased a few hours after reperfusion but grew markedly after day 1, consistent with the reports in rodents [24] and humans [4-6]. Although the T2-weighted FLAIR infarct volume of the transient MCAO group peaked at day 7, it was markedly smaller than that of the permanent MCAO group, indicating that reperfusion salvaged a substantial amount of tissue which provides evidence supporting the concept of the metabolism-flow mismatch in this stroke model. Comparing our results with the published results in rodents, infarct volume typically stopped evolving by 1 or 2 days after stroke [24]. This finding further corroborates the notion that ischemic evolution in human brains appears to be more similar to that seen in the NHP model than in rodent models.

Early post-ischemic hyperperfusion was detected in the transient MCAO group but not in the permanent MCAO group. This observation suggests that this NHP model could offer an opportunity to investigate hyperperfusion in stroke. Early post-ischemic hyperperfusion, a common phenomenon in human stroke patients [27], is an indicator of successful reperfusion. Controversy exists regarding whether early post-ischemic hyperperfusion is beneficial or harmful [27-29]. In the transient MCAO of this study, region with early post-ischemic hyperperfusion eventually developed into infarct, suggesting possible reperfusion injury. More extensive studies with this baboon stroke model might provide insights for developing intervention against reperfusion injury.

The major shortcomings of the current study are: 1) Reproducibility of the stroke model has not yet been established given the small sample sizes, 2) MRI during occlusion would be helpful but unfortunately, to our knowledge, there is no commercially available balloon catheter that is MRI compatible. The balloon catheter causes MRI susceptibility artifacts and cannot be used in the magnet. The cause of permanent MCAO after withdrawal of the balloon catheter was likely clots and/or vasospasm. Future baboon stroke studies will increase sample size to establish reproducibility, establish ADC and CBF viability thresholds, include other multimodal MRI methods (i.e. fMRI and pH MRI), investigate different MCAO durations to mimic various clinical conditions from hyperacute to chronic phase, evaluate functional reorganization in chronic stroke, and compare with immunohistology and behavioral/neurological scores. Future studies will also explore the embolic stroke model, which may better mimic clinical conditions albeit the infarct volumes produced will likely be more variable compared to the direct occlusion approach. The NHP stroke model is more expensive than the rodent model, so rodent stroke models will remain indispensable for initial testing of novel imaging modalities and emerging therapeutic interventions.  

CONCLUSION

Perfusion-diffusion mismatch, which approximates the ischemic penumbra, was detected in a clinically relevant, large non-human primate (baboon) stroke model.
Reperfusion salvaged substantial amount of mismatch tissue compared to permanent stroke. These initial findings offer encouraging results to further explore the baboon stroke model with multimodal MRI. There are a number of dissimilarities between rodent and human brains that may lead to differences in response to identical ischemic insults. The timing, dose and other aspects of pharmacokinetics in humans could not be easily extrapolated from rodent models, which may have contributed, in part, to the negative outcomes of some clinical trials on stroke treatments. Thus, this large NHP stroke model has the potential to accelerate clinical translations of novel therapeutics and imaging tools in stroke research.
